

CS 33

Machine Programming (4)

Some of the slides in this lecture are either from or adapted from slides provided by the authors of the textbook “Computer Systems: A Programmer’s Perspective,” 2nd Edition and are provided from the website of Carnegie-Mellon University, course 15-213, taught by Randy Bryant and David O’Hallaron in Fall 2010. These slides are indicated “Supplied by CMU” in the notes section of the slides.

Jumping

- **jX instructions**
 - Jump to different part of program depending on condition codes

jX	Condition	Description
jmp	1	Unconditional
je	ZF	Equal / Zero
jne	~ZF	Not Equal / Not Zero
js	SF	Negative
jns	~SF	Nonnegative
jg	~(SF^OF) & ~ZF	Greater (Signed)
jge	~(SF^OF)	Greater or Equal (Signed)
jl	(SF^OF)	Less (Signed)
jle	(SF^OF) ZF	Less or Equal (Signed)
ja	~CF & ~ZF	Above (unsigned)
jb	CF	Below (unsigned)

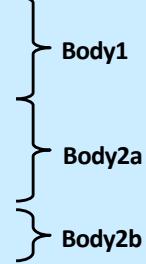

Supplied by CMU.

See the notes for slide 28.

Conditional-Branch Example

```
int absdiff(int x, int y)
{
    int result;
    if (x > y) {
        result = x-y;
    } else {
        result = y-x;
    }
    return result;
}
```

```
absdiff:
    movl %esi, %eax
    cmpl %esi, %edi
    jle .L6
    subl %eax, %edi
    movl %edi, %eax
    jmp .L7
.L6:
    subl %edi, %eax
.L7:
    ret
```

x in %edi

y in %esi

Supplied by CMU, but converted to x86-64.

The function computes the absolute value of the difference between its two arguments.

Conditional-Branch Example (Cont.)

```
int goto_ad(int x, int y)
{
    int result;
    if (x <= y) goto Else;
    result = x-y;
    goto Exit;
Else:
    result = y-x;
Exit:
    return result;
}
```

```
absdiff:
    movl %esi, %eax
    cmpl %esi, %edi
    jle .L6
    subl %eax, %edi
    movl %edi, %eax
    jmp .L7
.L6:
    subl %edi, %eax
.L7:
    ret
```

The assembly code is annotated with curly braces on the right side, grouping the instructions into three distinct regions:

- Body1:** Contains the instructions from `movl %esi, %eax` to `jmp .L7`.
- Body2a:** Contains the instructions from `subl %edi, %eax` to the label `.L6`.
- Body2b:** Contains the instructions from the label `.L6` to the `ret` instruction.

- C allows “goto” as means of transferring control
 - closer to machine-level programming style
- Generally considered bad coding style

Supplied by CMU, but converted to x86-64.

General Conditional-Expression Translation

C Code

```
val = Test ? Then_Expr : Else_Expr;
```

```
val = x>y ? x-y : y-x;
```

Goto Version

```
nt = !Test;
if (nt) goto Else;
val = Then_Expr;
goto Done;
Else:
    val = Else_Expr;
Done:
    . . .
```

- **Test** is expression returning integer
 - == 0 interpreted as false
 - ≠ 0 interpreted as true
- Create separate code regions for **then** and **else** expressions
- Execute appropriate one

Supplied by CMU.

C's conditional expression, as shown in the slide, is sometimes useful, but often results in really difficult-to-read code.

(There's an "International Obfuscated C Code Contest" (IOCCC) that awards prizes to those who use valid syntax to write the most difficult-to-understand implementations of simple functions. The conditional expression features prominently in winners' code. See <https://www.ioccc.org/.>)

“Do-While” Loop Example

C Code

```
int pcount_do(unsigned x)
{
    int result = 0;
    do {
        result += x & 0x1;
        x >>= 1;
    } while (x);
    return result;
}
```

Goto Version

```
int pcount_do(unsigned x)
{
    int result = 0;
loop:
    result += x & 0x1;
    x >>= 1;
    if (x)
        goto loop;
    return result;
}
```

- Count number of 1's in argument x (“popcount”)
- Use conditional branch either to continue looping or to exit loop

Supplied by CMU.

“Do-While” Loop Compilation

Goto Version

```
int pcount_do(unsigned x) {
    int result = 0;
loop:
    result += x & 0x1;
    x >= 1;
    if (x)
        goto loop;
    return result;
}
```

```
        movl $0, %eax      # result = 0
.L2:   # loop:
        movl %edi, %ecx
        andl $1, %ecx      # t = x & 1
        addl %ecx, %eax    # result += t
        shr1 %edi          # x >= 1
        jne .L2            # if !0, goto loop
```

Registers:

%edi	x
%eax	result

Supplied by CMU.

Note that the condition codes are set as part of the execution of the **shr1** instruction.

General “Do-While” Translation

C Code

```
do  
    Body  
    while (Test);
```

- **Body:** {

```
    Statement1;  
    Statement2;  
    ...  
    Statementn;  
}
```

- **Test returns integer**

= 0 interpreted as false
≠ 0 interpreted as true

Goto Version

```
loop:  
    Body  
    if (Test)  
        goto loop
```

Supplied by CMU.

“While” Loop Example

C Code

```
int pcount_while(unsigned x) {  
    int result = 0;  
    while (x) {  
        result += x & 0x1;  
        x >>= 1;  
    }  
    return result;  
}
```

Goto Version

```
int pcount_do(unsigned x) {  
    int result = 0;  
    if (!x) goto done;  
loop:  
    result += x & 0x1;  
    x >>= 1;  
    if (x)  
        goto loop;  
done:  
    return result;  
}
```

- Is this code equivalent to the do-while version?
 - must jump out of loop if test fails

General “While” Translation

While version

```
while (Test)
  Body
```

Do-While Version

```
if (!Test)
  goto done;
do
  Body
  while(Test);
done:
```

Goto Version

```
if (!Test)
  goto done;
loop:
  Body
  if (Test)
    goto loop;
done:
```

Supplied by CMU.

“For” Loop Example

C Code

```
#define WSIZE 8*sizeof(int)
int pcount_for(unsigned x) {
    int i;
    int result = 0;
    for (i = 0; i < WSIZE; i++) {
        unsigned mask = 1 << i;
        result += (x & mask) != 0;
    }
    return result;
}
```

- Is this code equivalent to other versions?

“For” Loop Form

General Form

```
for (Init; Test; Update)
```

Body

```
for (i = 0; i < WSIZE; i++) {  
    unsigned mask = 1 << i;  
    result += (x & mask) != 0;  
}
```

Init

```
i = 0
```

Test

```
i < WSIZE
```

Update

```
i++
```

Body

```
{  
    unsigned mask = 1 << i;  
    result += (x & mask) != 0;  
}
```

Supplied by CMU.

“For” Loop → While Loop

For Version

```
for (Init; Test; Update)  
    Body
```

While Version

```
Init;  
while (Test) {  
    Body  
    Update;  
}
```

XII-13

Supplied by CMU.

“For” Loop → ... → Goto

For Version

```
for (Init; Test; Update)  
    Body
```

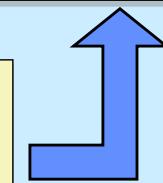

While Version

```
Init;  
while (Test) {  
    Body  
    Update;  
}
```

```
Init;  
if (!Test)  
    goto done;  
loop:  
    Body  
    Update  
    if (Test)  
        goto loop;  
done:
```

```
Init;  
if (!Test)  
    goto done;  
do  
    Body  
    Update  
    while(Test);  
done:
```

Supplied by CMU.

“For” Loop Conversion Example

C Code

```
#define WSIZE 8*sizeof(int)
int pcount_for(unsigned x) {
    int i;
    int result = 0;
    for (i = 0; i < WSIZE; i++) {
        unsigned mask = 1 << i;
        result += (x & mask) != 0;
    }
    return result;
}
```

Initial test can be optimized away

Goto Version

```
int pcount_for_gt(unsigned x) {
    int i;
    int result = 0;           Init
    i = 0;                   !Test
    if (!(i < WSIZE))
        goto done;
loop:                      Body
{
    unsigned mask = 1 << i;
    result += (x & mask) != 0;
}
i++;                      Update
if (i < WSIZE) Test
    goto loop;
done:
    return result;
}
```

Switch-Statement Example

```
long switch_eg (long m, long d) {
    if (d < 1) return 0;
    switch(m) {
        case 1: case 3: case 5:
        case 7: case 8: case 10:
        case 12:
            if (d > 31) return 0;
            else return 1;
        case 2:
            if (d > 28) return 0;
            else return 1;
        case 4: case 6: case 9:
        case 11:
            if (d > 30) return 0;
            else return 1;
        default:
            return 0;
    }
    return 0;
}
```

Code very much like this appears in level three of the traps project.

Offset Structure

Switch Form

```
switch(x) {  
    case val_0:  
        Block 0  
    case val_1:  
        Block 1  
        ...  
    case val_n-1:  
        Block n-1  
}
```

Jump Offset Table

Otab:	Targ0 Offset
	Targ1 Offset
	Targ2 Offset
	•
	•
	•
	Targn-1 Offset

Jump Targets

Targ0:	Code Block 0
Targ1:	Code Block 1
Targ2:	Code Block 2
•	•
•	•
Targn-1:	Code Block n-1

Approximate Translation

```
target = Otab + OTab[x];  
goto *target;
```

Adapted from slide supplied by CMU to account for changes in gcc.

The translation is “approximate” because C doesn’t have the notion of the target of a goto being a variable. But, if it did, then the translation is what we’d want!

Otab (for “offset table”) is a table of relative address of the jump targets. The idea is, given a value of x, **Otab[x]** contains a reference to the code block that should be handled for that case in the switch statement (this code block is known as the **jump target**). These references are offsets from the address **Otab**. In other words, **Otab** is an address, if we add to it the offset of a particular jump target, we get the absolute address of that jump target.

Assembler Code (1)

```
switch_eg:  
    movl    $0, %eax  
    testq   %rsi, %rsi  
    jle     .L1  
    cmpq    $12, %rdi  
    ja      .L8  
    leaq    .L4(%rip), %rdx  
    movslq  (%rdx,%rdi,4), %rax  
    addq    %rdx, %rax  
    jmp     *%rax  
  
.section      .rodata  
.align 4  
.L4:  
    .long   .L8-.L4  
    .long   .L3-.L4  
    .long   .L6-.L4  
    .long   .L3-.L4  
    .long   .L3-.L4  
    .long   .L5-.L4  
    .long   .L3-.L4  
    .long   .L5-.L4  
    .long   .L3-.L4  
    .long   .L5-.L4  
    .long   .L3-.L4  
    .text
```

Here's the assembler code obtained by compiling our C code in gcc with the -O1 optimization flag (specifying that some, but not lots of optimization should be done). We explain this code in subsequent slides. The jump offset table starts at label .L4.

Assembler Code (2)

```
.L3:           .L5:
    cmpq    $31, %rsi      cmpq    $30, %rsi
    setle   %al          setle   %al
    movzbl  %al, %eax    movzbl  %al, %eax
    ret                 ret

.L6:           .L8:
    cmpq    $28, %rsi      movl    $0, %eax
    setle   %al          .L1:
    movzbl  %al, %eax    ret
```

Assembler Code Explanation (1)

```
switch_eg:  
    movl    $0, %eax    # return value set to 0  
    testq  %rsi, %rsi  # sets cc based on %rsi & %rsi  
    jle    .L1          # go to L1, where it returns 0  
    cmpq    $12, %rdi  
    ja     .L8  
    leaq    .L4(%rip), %rdx  
    movslq (%rdx,%rdi,4), %rax  
    addq    %rdx, %rax  
    jmp    *%rax
```

- **testq %rsi, %rsi**
 - sets cc based on the contents of %rsi (d)
 - **jle**
 - jumps if $(SF \wedge OF) \mid ZF$
 - OF is not set
 - jumps if SF or ZF is set (i.e., < 1)

The first three instructions cause control to go to .L1 if the second argument (d) is less than 1. At .L1 is code that simply returns (with a return value of 0).

Assembler Code Explanation (2)

```
switch_eg:  
    movl    $0, %eax      # return value set to 0  
    testq   %rsi, %rsi    # sets cc based on %rsi & %rsi  
    jle     .L1           # go to L1, where it returns 0  
    cmpq    $12, %rdi     # %rdi : 12  
    ja      .L8           # go to L8 if %rdi > 12 or < 0  
    leaq    .L4(%rip), %rdx  
    movslq  (%rdx,%rdi,4), %rax  
    addq    %rdx, %rax  
    jmp    *%rax  
  
• ja .L8  
  • unsigned comparison, though m is signed!  
  • jumps if %rdi > 12  
  • also jumps if %rdi is negative
```

The next two instructions simply check to make sure that %rdi (the first argument, m) is less than or equal to 12. If not, control goes to .L8, which sets the return value to 0 and returns. Of course, the return value (in %rax/%eax) is already zero, so setting it to zero again is unnecessary.

Note that we're using **ja** (jump if above), which is normally used after comparing unsigned values. The first argument, m, is a (signed) **long**. But if it is interpreted as an unsigned value, then if the leftmost bit (the sign bit) is set, it appears to be a very large unsigned value, and thus the jump is taken.

Assembler Code Explanation (3)

```
switch_eg:  
    movl    $0, %eax  
    testq   %rsi, %rsi  
    jle     .L1  
    cmpq    $12, %rdi  
    ja      .L8  
    leaq    .L4(%rip), %rdx  
    movslq  (%rdx,%rdi,4), %rax  
    addq    %rdx, %rax  
    jmp     *%rax  
  
.section  .rodata  
.align 4  
.L4:  
.long   .L8-.L4 # m=0  
.long   .L3-.L4 # m=1  
.long   .L6-.L4 # m=2  
.long   .L3-.L4 # m=3  
.long   .L5-.L4 # m=4  
.long   .L3-.L4 # m=5  
.long   .L5-.L4 # m=6  
.long   .L3-.L4 # m=7  
.long   .L3-.L4 # m=8  
.long   .L5-.L4 # m=9  
.long   .L3-.L4 # m=10  
.long   .L5-.L4 # m=11  
.long   .L3-.L4 # m=12  
.text
```

The table on the right is known as an **offset table**. Each line refers to the code to be executed for the corresponding value of m. Each entry in the table is a long (recall that in x86-64 assembler, long means 32 bits). The value of each entry is the difference between the address of the table (.L4) and the address of the code to be executed for a particular value of m (the other .L labels). Thus each entry is the distance (or offset) from the beginning of the table to the code for each case. Note that this offset will be negative, as explained below. It's assumed that the offset fits in a 32-bit signed quantity (which the system guarantees to be true.)

One might ask why we put 32-bit offsets in the table rather than 64-bit addresses. The reason is to reduce the size of these tables – if we used addresses, they'd be twice the size.

This table is not executable (it just contains offsets), but it should be treated as read-only – its contents will never change. The directive “.section .rodata” tells the assembler that we want this table to be located in memory that is read-only, but not executable. The directive at the end of the table (“.text”) tells the assembler that what follows is (again) executable code. This read-only, non-executable memory is located at a higher address than the executable code is (accept this as a fact for now, we'll see later why it is so). Thus the offsets in the table are negative.

The highlighted code on the left is what interprets the table, We examine it next.

Assembler Code Explanation (4)

```
switch_eg:  
    movl    $0, %eax  
    testq   %rsi, %rsi  
    jle     .L1  
    cmpq    $12, %rdi  
    ja      .L8  
    leaq    .L4(%rip), %rdx  
    movslq  (%rdx,%rdi,4), %rax  
    addq    %rdx, %rax  
    jmp    *%rax  
.L4:  
    .long   .L8-.L4 # m=0  
    .long   .L3-.L4 # m=1  
    .long   .L6-.L4 # m=2  
    .long   .L3-.L4 # m=3  
    .long   .L5-.L4 # m=4  
    .long   .L3-.L4 # m=5  
    .long   .L5-.L4 # m=6  
    .long   .L3-.L4 # m=7  
    .long   .L3-.L4 # m=8  
    .long   .L5-.L4 # m=9  
    .long   .L3-.L4 # m=10  
    .long   .L5-.L4 # m=11  
    .long   .L3-.L4 # m=12  
.text
```

The highlighted code makes use of an indirect jump instruction, indicated by having an asterisk before its register operand. The register contains an address, and the jump is made to the code at that address. Note that jump instructions that are not indirect have constants as their operands. We'll see later on that, because of this, indirect jumps are often much slower than non-indirect jumps.

Assembler Code Explanation (5)

```
switch_eg:  
    movl    $0, %eax  
    testq   %rsi, %rsi  
    jle     .L1  
    cmpq    $12, %rdi  
    ja      .L8  
    leaq    .L4(%rip), %rdx  
    movslq  (%rdx,%rdi,4), %rax  
    addq    %rdx, %rax  
    jmp     *%rax  
  
.section    .rodata  
.align 4  
.L4:  
.long     .L8-.L4 # m=0  
.long     .L3-.L4 # m=1  
.long     .L6-.L4 # m=2  
.long     .L3-.L4 # m=3  
.long     .L5-.L4 # m=4  
.long     .L3-.L4 # m=5  
.long     .L5-.L4 # m=6  
.long     .L3-.L4 # m=7  
.long     .L3-.L4 # m=8  
.long     .L5-.L4 # m=9  
.long     .L3-.L4 # m=10  
.long    .L5-.L4 # m=11  
.long    .L3-.L4 # m=12  
.text
```

The **leaq** instruction (load effective address, quad), performs an address computation, but rather than fetching the data at the address, it stores the address itself in %rdx.

What's unusual about the instruction is that it uses %rip (the instruction pointer) as the base register, and has a displacement that is a label. This is a special case for the assembler, which can compute the offset between the leaq instruction and the label, and use that value for the displacement field. Thus the instruction puts the address of the offset table (.L4) into %rdx.

Assembler Code Explanation (6)

```
switch_eg:  
    movl    $0, %eax  
    testq   %rsi, %rsi  
    jle     .L1  
    cmpq    $12, %rdi  
    ja      .L8  
    leaq    .L4(%rip), %rdx  
    movslq  (%rdx,%rdi,4), %rax  
    addq    %rdx, %rax  
    jmp     *%rax  
  
.section    .rodata  
.align 4  
.L4:  
.long     .L8-.L4 # m=0  
.long     .L3-.L4 # m=1  
.long     .L6-.L4 # m=2  
.long     .L3-.L4 # m=3  
.long     .L5-.L4 # m=4  
.long     .L3-.L4 # m=5  
.long     .L5-.L4 # m=6  
.long     .L3-.L4 # m=7  
.long     .L3-.L4 # m=8  
.long     .L5-.L4 # m=9  
.long     .L3-.L4 # m=10  
.long    .L5-.L4 # m=11  
.long    .L3-.L4 # m=12  
.text
```

The **movslq** instruction copies a long (32 bits) into a quad (64 bits), and does sign extension so as to preserve the sign of the value being copied.

%rdi contains m, the first argument, which is also the argument of the switch statement. We use it to index into the offset table: As we saw in the previous slide, %rdx contains the address of the table, whose entries are each 4 bytes long. Thus we use %rdi as an index register, with a scale factor of 4. The contents of that entry (which is the distance from the table to the code that should be executed to handle this case) is copied into %rax, using sign extension to fill the register.

Assembler Code Explanation (7)

```
switch_eg:  
    movl    $0, %eax  
    testq   %rsi, %rsi  
    jle     .L1  
    cmpq    $12, %rdi  
    ja      .L8  
    leaq    .L4(%rip), %rdx  
    movslq  (%rdx,%rdi,4), %rax  
    addq    %rdx, %rax  
    jmp    *%rax  
  
.section    .rodata  
.align 4  
.L4:  
.long    .L8-.L4 # m=0  
.long    .L3-.L4 # m=1  
.long    .L6-.L4 # m=2  
.long    .L3-.L4 # m=3  
.long    .L5-.L4 # m=4  
.long    .L3-.L4 # m=5  
.long    .L5-.L4 # m=6  
.long    .L3-.L4 # m=7  
.long    .L3-.L4 # m=8  
.long    .L5-.L4 # m=9  
.long    .L3-.L4 # m=10  
.long   .L5-.L4 # m=11  
.long   .L3-.L4 # m=12  
.text
```

The offset of the code we want to jump to is in %rax. To convert this offset into an absolute address, we need to add to it the address of the table. That's what the **addq** instruction does.

We can now do the indirect jump, to the address contained in %rax.

Switch Statements and Traps

- The code we just looked at was compiled with gcc's O1 flag
 - a moderate amount of “optimization”
- Traps was compiled with the O1 flag
 - no optimization
- O0 often produces easier-to-read (but less efficient) code
 - not so for switch

Gdb and Switch (1)

```
B+ 0x5555555555165 <switch_eg>      mov    $0x0,%eax
0x555555555516a <switch_eg+5>       test   %rsi,%rsi
0x555555555516d <switch_eg+8>       jle    0x55555555551ab <switch_eg+70>
0x555555555516f <switch_eg+10>      cmp    $0xc,%rdi
0x5555555555173 <switch_eg+14>      ja    0x55555555551a6 <switch_eg+65>
0x5555555555175 <switch_eg+16>      lea    0xe88(%rip),%rdx # 0x555555556004
0x555555555517c <switch_eg+23>      movslq (%rdx,%rdi,4),%rax
0x5555555555180 <switch_eg+27>      add    %rdx,%rax
>0x5555555555183 <switch_eg+30>     jmp    *%rax
0x5555555555185 <switch_eg+32>      cmp    $0x1f,%rsi
0x5555555555189 <switch_eg+36>      setle %al
0x555555555518c <switch_eg+39>      movzbl %al,%eax
0x555555555518f <switch_eg+42>      ret
```

```
(gdb) x/14dw $rdx
0x555555556004: -3678    -3711    -3700    -3711
0x555555556014: -3689    -3711    -3689    -3711
0x555555556024: -3711    -3689    -3711    -3689
0x555555556034: -3711    1734439765
```

So, now that we know how switch statements are implemented, how might we "reverse engineer" object code to figure out the switch statement it implements?

Here we're running gdb on a program that contains a call to **switch_eg**. We gave the command "layout asm" so that we can see the assembly listing at the top of the slide. We set a breakpoint at **switch_eg**.

Assuming no knowledge of the original source code, we look at the code for **switch_eg** and see an indirect jump instruction at `switch_eg+30`, which is a definite indication that the C code contained a switch statement. We can see that `%rdx` contains the address of the offset table, and that `%rax` will be set to the entry in the table at the index given in `%rdi`. The contents of `%rdx` are added to `%rax`, thus causing `%rax` to point to the instruction the indirect jump will go to.

Note also that for **leaq** instructions in which the base register is `%rip`, gdb indicates (as a comment) what the computed address is (`0x555555556004` in this case, which is the address of the offset table).

So, with all this in mind, after the breakpoint was reached, we issued the **stepi** (si) command 8 times so that we could see the values of all registers just before the indirect jmp. We then used the **x/14dw** gdb command to print 14 entries of a jump offset table starting at the address contained in `%rdx`. We had to guess how many entries there are – 14 seems reasonable in that it seems unlikely that a switch statement has more than 14 cases, though it might. We know that the table comes after the executable code, so the

entries are negative. We see seven entries with values reasonably close to one another, while the remaining entry is very different, so we conclude that the jump table contains 13 entries.

Gdb and Switch (2)

```
>0x5555555555183 <switch_eg+30> jmp    *%rax
0x5555555555185 <switch_eg+32> cmp    $0x1f,%rsi ← Offset -3711
0x5555555555189 <switch_eg+36> setle  %al
0x555555555518c <switch_eg+39> movzbl %al,%eax
0x555555555518f <switch_eg+42> ret
0x5555555555190 <switch_eg+43> cmp    $0x1c,%rsi
0x5555555555194 <switch_eg+47> setle  %al
0x5555555555197 <switch_eg+50> movzbl %al,%eax
0x555555555519a <switch_eg+53> ret
0x555555555519b <switch_eg+54> cmp    $0x1e,%rsi
0x555555555519f <switch_eg+58> setle  %al
0x55555555551a2 <switch_eg+61> movzbl %al,%eax
0x55555555551a5 <switch_eg+64> ret
0x55555555551a6 <switch_eg+65> mov    $0x0,%eax
0x55555555551ab <switch_eg+70> ret
```

```
(gdb) x/14dw $rdx
0x555555556004: -3678  -3711  -3700  -3711
0x555555556014: -3689  -3711  -3689  -3711
0x555555556024: -3711  -3689  -3711  -3689
0x555555556034: -3711  1734439765
```

The code for some case of the switch should come immediately after the **jmp** (what else would go there?!). So the smallest (most negative) offset in the jump offset table must be the offset for this first code segment. Thus offset -3711 corresponds to switch_eg+32 in the assembly listing. It's at indices 1, 3, 5, 7, 8, 10, and 12 of the table, so it's this code that's executed when the first argument of switch_eg is 1, 3, 5, 7, 8, 10, or 12.

Knowing this, we can figure out the rest. The slide contains all the code of switch_eg from the indirect jump to the end of the function (and thus the code for all the cases of the switch statement).

Quiz 1

What C code would you compile to get the following assembler code?

```
    movq    $0, %rax
.L2:
    movq    %rax, a(,%rax,8)
    addq    $1, %rax
    cmpq    $10, %rax
    jl     .L2
    ret
```

a

```
long a[10];
void func() {
    long i=0;
    while (i<10)
        a[i]= i++;
}
```

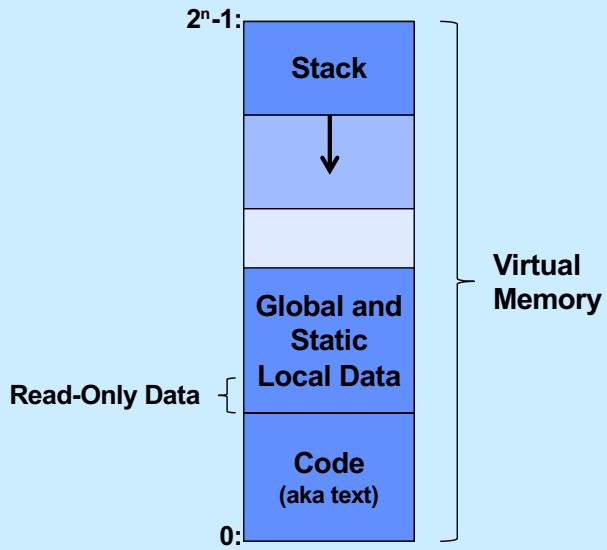

b

```
long a[10];
void func() {
    long i;
    for (i=0; i<10; i++)
        a[i]= 1;
}
```

c

```
long a[10];
void func() {
    long i=0;
    switch (i) {
case 0:
    a[i] = 0;
    break;
default:
    a[i] = 10
    }
}
```

Digression (Again): Where Stuff Is (Roughly)

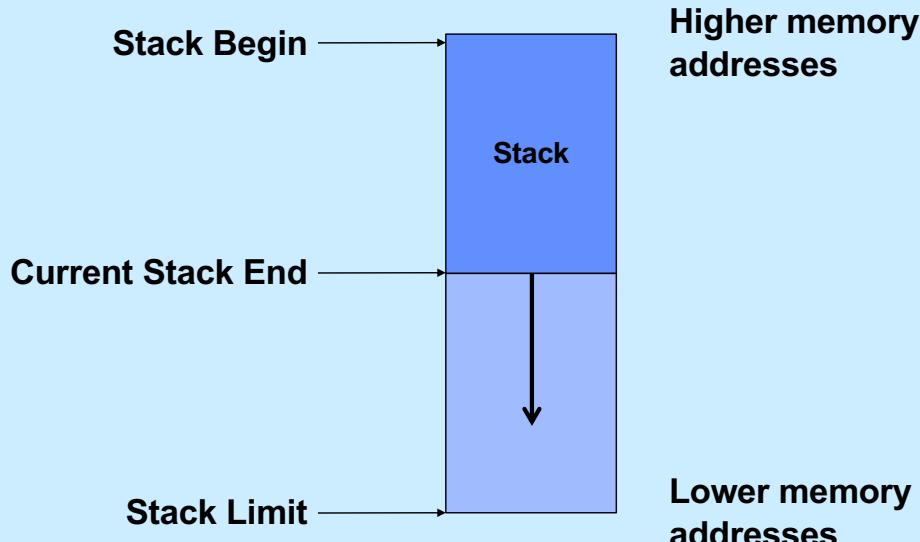

Here we revisit the slide we saw a few weeks ago, this time drawing it with high addresses at the top and low addresses at the bottom. The point is that a large amount of virtual memory is reserved for the stack. In most cases there's plenty of room for the stack and we don't have to worry about exceeding its bounds. However, if we do exceed its bounds (by accessing memory outside of what's been allocated), the program will get a seg fault.

Note that read-only data (such as the offset tables used for switch statements) is placed just above the executable code.

Function Call and Return

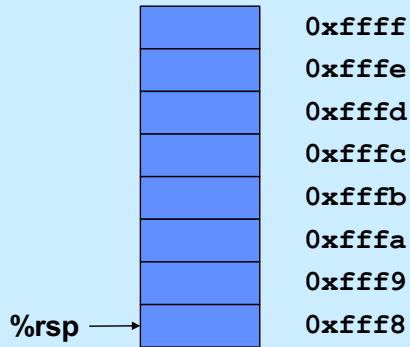

- **Function A calls function B**
 - **Function B calls function C**
- ... several million instructions later**
- **C returns**
 - how does it know to return to B?
 - **B returns**
 - how does it know to return to A?

The Runtime Stack

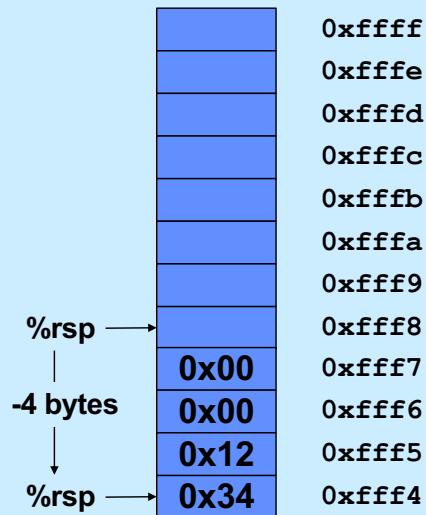

Stacks, as implemented on the X86 for most operating systems (and, in particular, Linux, OSX, and Windows) grow "downwards", from high memory addresses to low memory addresses. To avoid confusion, we will not use the words "top of stack" or "bottom of stack" but will instead use "stack begin" and "current stack end". The total amount of memory available for the stack is that between the beginning of the stack and the "stack limit". When the stack end reaches the stack limit, we're out of memory for the stack.

Stack Operations

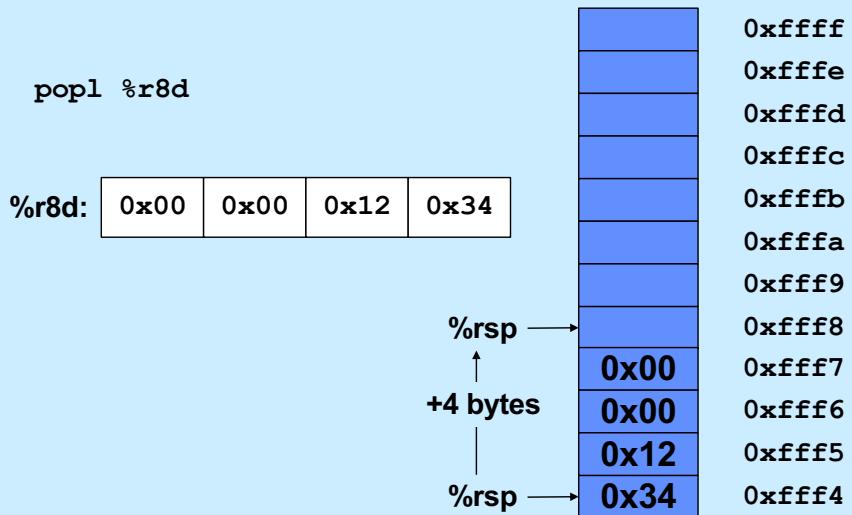

Push

```
pushl $0x1234
```

Here we execute **pushl** to push a 4-byte item onto the end of the stack. First %rsp is decremented by 4 bytes, then the item is copied into the 4-byte location now pointed to by %rsp.

Pop

```
0x2000: func:  
          ... ...  
0x2200: movq $6, %rax  
0x2203: ret  
0x1000: call func  
0x1004: addq $3, %rax
```

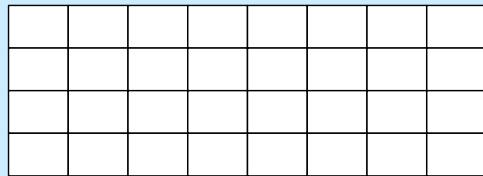

When a function is called (using the **call** instruction), the (8-byte) address of the instruction just after the **call** (the "return address") is pushed onto the stack. Then when the called function returns (via the **ret** instruction), the 8-byte address at the end of the stack (pointed to by `%rsp`) is copied into the instruction pointer (`%rip`), thus causing control to resume at the instruction following the original call.

Call and Return

```
0x2000: func:  
...  
0x2200: movq $6, %rax  
0x2203: ret
```

→ 0x1000: call func
0x1004: addq \$3, %rax

stack growth ↓

0xfffff10018
0xfffff10010
0xfffff10008
0xfffff10000 ←

%							
00	00	00	00	00	00	10	00
00	00	00	0f	ff	f1	00	00

%rax
%rip
%rsp

Here we begin walking through what happens during a call and return.

Initially, %rip (the instruction pointer – what it points to is shown with a red arrow pointing to the right) points to the call instruction – thus it's the next instruction to be executed. %rsp (the stack pointer, shown with a green arrow pointing to the left) points to the current end of the stack. The actual values contained in the relevant registers are shown at the bottom of the slide (%rax isn't relevant yet, but will be soon!).

Call and Return

```
0x1000: call func  
0x1004: addq $3, %rax
```

```
→ 0x2000: func:  
...  
0x2200: movq $6, %rax  
0x2203: ret
```

stack growth ↓

00	00	00	00	00	00	10	04

0xfffff10018
0xfffff10010
0xfffff10008
0xfffff10000
0xfffff0fff8 ←

00	00	00	00	00	00	20	00
00	00	00	0f	ff	f0	ff	f8

%rax
%rip
%rsp

When the **call** instruction is executed, the address of the instruction after the **call** is pushed onto the stack. Thus %rsp is decremented by eight and 0x1004 is copied to the 8-byte location that is now at the end of the stack. The instruction pointer, %rip, now points to the first instruction of **func**.

Call and Return

```
0x1000: call func  
0x1004: addq $3, %rax
```

```
0x2000: func:  
...  
0x2200: movq $6, %rax  
0x2203: ret
```

stack growth ↓

00	00	00	00	00	00	10	04

0xfffff10018
0xfffff10010
0xfffff10008
0xfffff10000
0xfffff0fff8 ←

00	00	00	00	00	00	00	06
00	00	00	00	00	00	22	03
00	00	00	0f	ff	f0	ff	f8

%rax

%rip

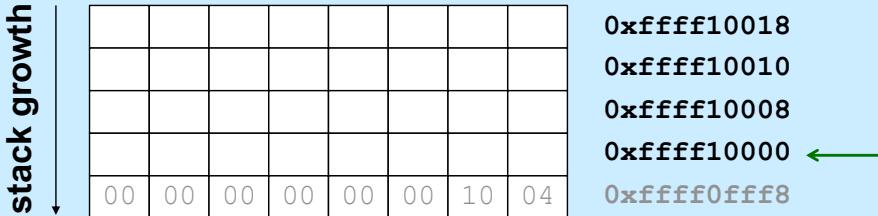

%rsp

Our function **func** puts its return value (6) into %rax, then executes the **ret** instruction. At this point, the address of the instruction following the **call** is at the end of the stack.

Call and Return

```
0x2000: func:  
...  
0x2200: movq $6, %rax  
0x2203: ret
```

```
0x1000: call func  
→ 0x1004: addq $3, %rax
```

00	00	00	00	00	00	00	06	%rax
00	00	00	00	00	00	10	04	%rip
00	00	00	0f	ff	f1	00	00	%rsp

The address at the end of the stack (0x1004) is popped off the stack and into %rip. Thus execution resumes at the instruction following the **call** and %rsp is incremented by 8. The function's return value is in %rax, for access by its caller.

Arguments and Local Variables (C Code)

```
int mainfunc() {                                long ASum(long *a,
    long array[3] =                           unsigned long size) {
        {2,117,-6};                         long i, sum = 0;
    long sum =                               for (i=0; i<size; i++)
        ASum(array, 3);                     sum += a[i];
    ...                                       return sum;
    return sum;                                }
}
```

- Local variables usually allocated on stack
- Arguments to functions pushed onto stack
- Local variables may be put in registers (and thus not on stack)

We explore these two functions in the next set of slides, looking at how arguments and local variables are stored on the stack. Note that the approach of storing arguments on the stack is used on the IA32 architecture, and on the x86-64 architecture when the -O0 optimization flag (meaning no optimization) is given to gcc.

Arguments and Local Variables (1)

```
mainfunc:  
    pushq %rbp          # save old %rbp  
    movq %rsp, %rbp      # set %rbp to point to stack frame  
    subq $32, %rsp       # alloc. space for locals (array and sum)  
    movq $2, -32(%rbp)   # initialize array[0]  
    movq $117, -24(%rbp) # initialize array[1]  
    movq $-6, -16(%rbp)  # initialize array[2]  
    pushq $3             # push arg 2  
    leaq -32(%rbp), %rax # array address is put in %rax  
    pushq %rax            # push arg 1  
    call ASum  
    addq $16, %rsp         # pop args  
    movq %rax, -8(%rbp)   # copy return value to sum  
    ...  
    addq $32, %rsp         # pop locals  
    popq %rbp              # pop and restore old %rbp  
    ret
```

Here we have compiled code for **mainfunc**. We'll work through this in detail in upcoming slides.

A function's stack frame is that part of the stack that holds its arguments, local variables, etc. In this example code, register %rbp points to a known location towards the beginning of the stack frame so that the arguments and local variables are located as offsets from what %rbp points to.

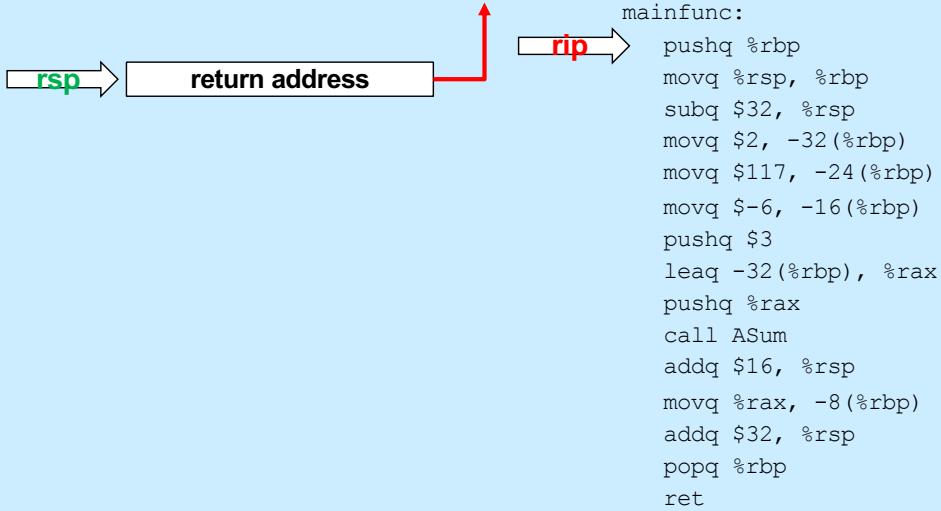

Note, as will be explained, this is not what one would see when compiling it for department computers, on which arguments are passed using registers.

Arguments and Local Variables (2)

```
ASum:  
    pushq %rbp          # save old %rbp  
    movq %rsp, %rbp      # set %rbp to point to stack frame  
    movq $0, %rcx         # i in %rcx  
    movq $0, %rax         # sum in %rax  
    movq 16(%rbp), %rdx      # copy arg 1 (array) into %rdx  
  
loop:  
    cmpq 24(%rbp), %rcx      # i < size?  
    jge done  
    addq (%rdx,%rcx,8), %rax    # sum += a[i]  
    incq %rcx            # i++  
    ja loop  
  
done:  
    popq %rbp          # pop and restore %rbp  
    ret
```

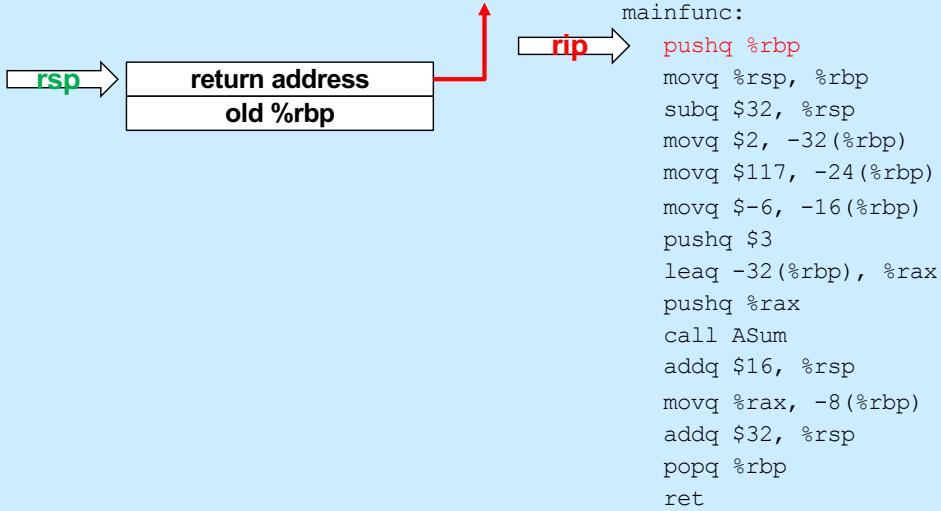

And here is the compiled code for **ASum**. The same caveats as given for the previous slide apply to this one as well.

Enter mainfunc

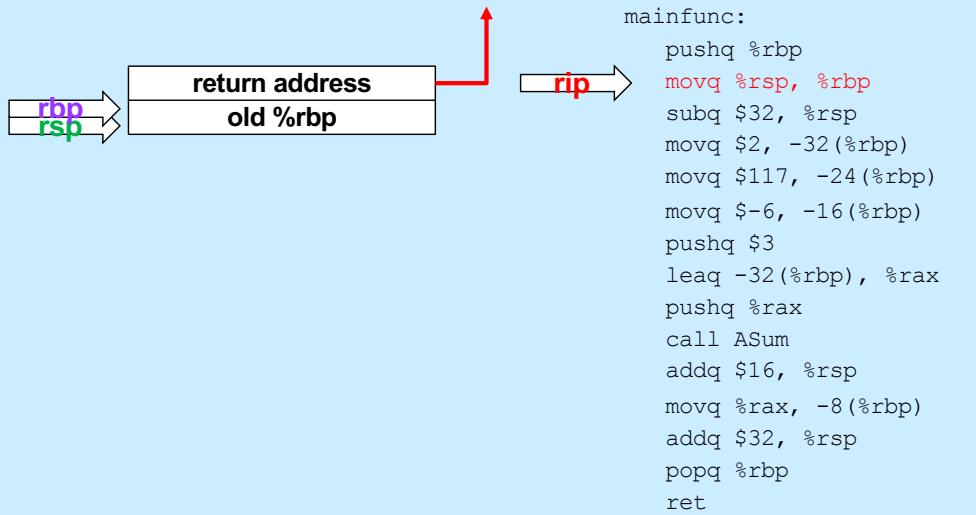

On entry to **mainfunc**, %rsp points to the caller's return address.

Enter mainfunc

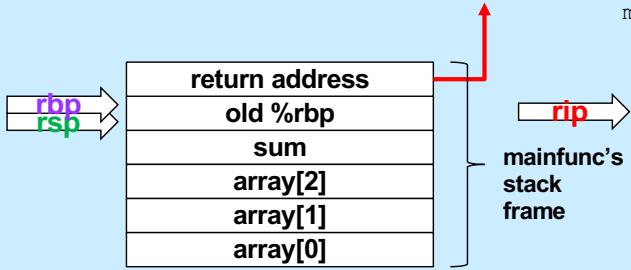

On entry to **mainfunc**, %rsp points to the caller's return address.

Setup Frame

The first thing done by **mainfunc** is to save the caller's %rbp by pushing it onto the stack.

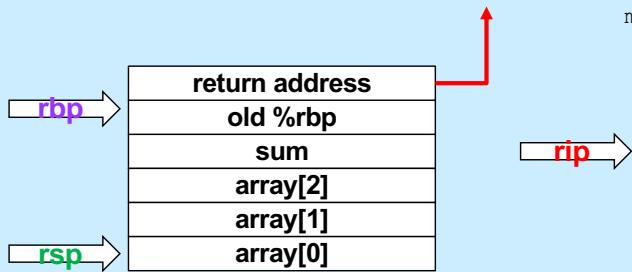

Allocate Local Variables

```
mainfunc:  
    pushq %rbp  
    movq %rsp, %rbp  
    subq $32, %rsp  
    movq $2, -32(%rbp)  
    movq $117, -24(%rbp)  
    movq $-6, -16(%rbp)  
    pushq $3  
    leaq -32(%rbp), %rax  
    pushq %rax  
    call ASum  
    addq $16, %rsp  
    movq %rax, -8(%rbp)  
    addq $32, %rsp  
    popq %rbp  
    ret
```

Next, space for **mainfunc**'s local variables is allocated on the stack by decrementing %rsp by their total size (32 bytes). At this point we have **mainfunc**'s stack frame in place.

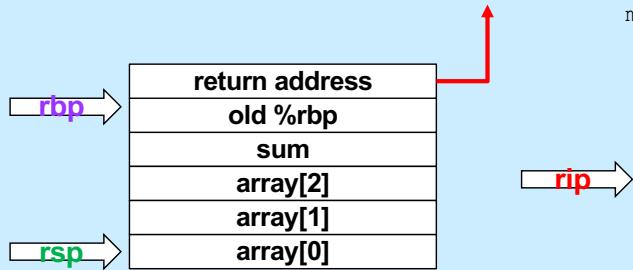

Initialize Local Array

```
mainfunc:  
    pushq %rbp  
    movq %rsp, %rbp  
    subq $32, %rsp  
    movq $2, -32(%rbp)  
    movq $117, -24(%rbp)  
    movq $-6, -16(%rbp)  
    pushq $3  
    leaq -32(%rbp), %rax  
    pushq %rax  
    call ASum  
    addq $16, %rsp  
    movq %rax, -8(%rbp)  
    addq $32, %rsp  
    popq %rbp  
    ret
```

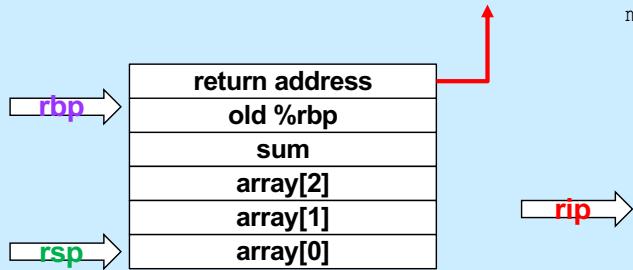

ASum now initializes the stack space containing its local variables.

Initialize Local Array

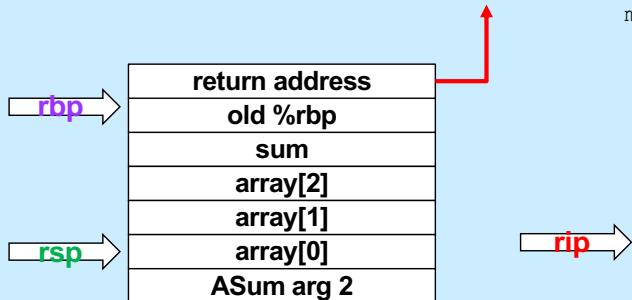

```
mainfunc:  
    pushq %rbp  
    movq %rsp, %rbp  
    subq $32, %rsp  
    movq $2, -32(%rbp)  
    movq $117, -24(%rbp)  
    movq $-6, -16(%rbp)  
    pushq $3  
    leaq -32(%rbp), %rax  
    pushq %rax  
    call ASum  
    addq $16, %rsp  
    movq %rax, -8(%rbp)  
    addq $32, %rsp  
    popq %rbp  
    ret
```

Initialize Local Array

```
mainfunc:  
    pushq %rbp  
    movq %rsp, %rbp  
    subq $32, %rsp  
    movq $2, -32(%rbp)  
    movq $117, -24(%rbp)  
    movq $-6, -16(%rbp)  
    pushq $3  
    leaq -32(%rbp), %rax  
    pushq %rax  
    call ASum  
    addq $16, %rsp  
    movq %rax, -8(%rbp)  
    addq $32, %rsp  
    popq %rbp  
    ret
```

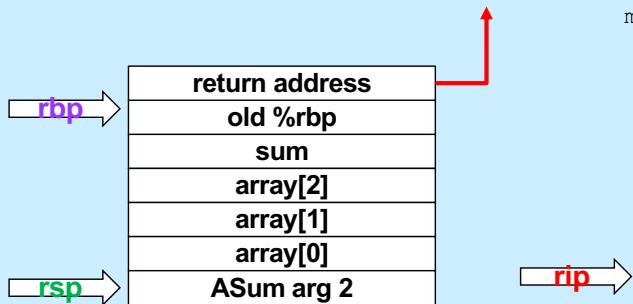

Push Second Argument

```
mainfunc:  
    pushq %rbp  
    movq %rsp, %rbp  
    subq $32, %rsp  
    movq $2, -32(%rbp)  
    movq $117, -24(%rbp)  
    movq $-6, -16(%rbp)  
    pushq $3  
    leaq -32(%rbp), %rax  
    pushq %rax  
    call ASum  
    addq $16, %rsp  
    movq %rax, -8(%rbp)  
    addq $32, %rsp  
    popq %rbp  
    ret
```

The second argument (3) to **ASum** is pushed onto the stack.

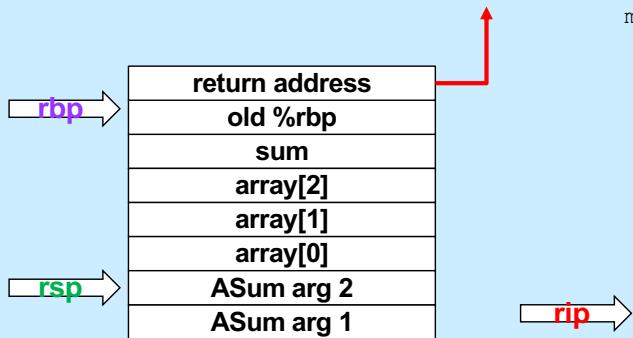

Get Array Address

```
mainfunc:  
    pushq %rbp  
    movq %rsp, %rbp  
    subq $32, %rsp  
    movq $2, -32(%rbp)  
    movq $117, -24(%rbp)  
    movq $-6, -16(%rbp)  
    pushq $3  
    leaq -32(%rbp), %rax  
    pushq %rax  
    call ASum  
    addq $16, %rsp  
    movq %rax, -8(%rbp)  
    addq $32, %rsp  
    popq %rbp  
    ret
```

In preparation for pushing the first argument to **ASum** onto the stack, the address of the array is put into **%rax**.

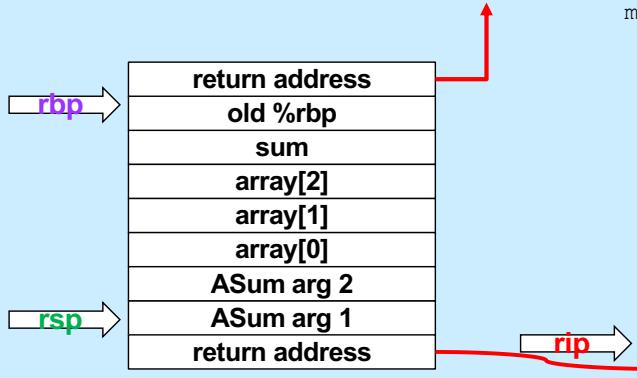

Push First Argument

```
mainfunc:  
    pushq %rbp  
    movq %rsp, %rbp  
    subq $32, %rsp  
    movq $2, -32(%rbp)  
    movq $117, -24(%rbp)  
    movq $-6, -16(%rbp)  
    pushq $3  
    leaq -32(%rbp), %rax  
    pushq %rax  
    call ASum  
    addq $16, %rsp  
    movq %rax, -8(%rbp)  
    addq $32, %rsp  
    popq %rbp  
    ret
```

And finally, the address of the array is pushed onto the stack as **ASum**'s first argument.

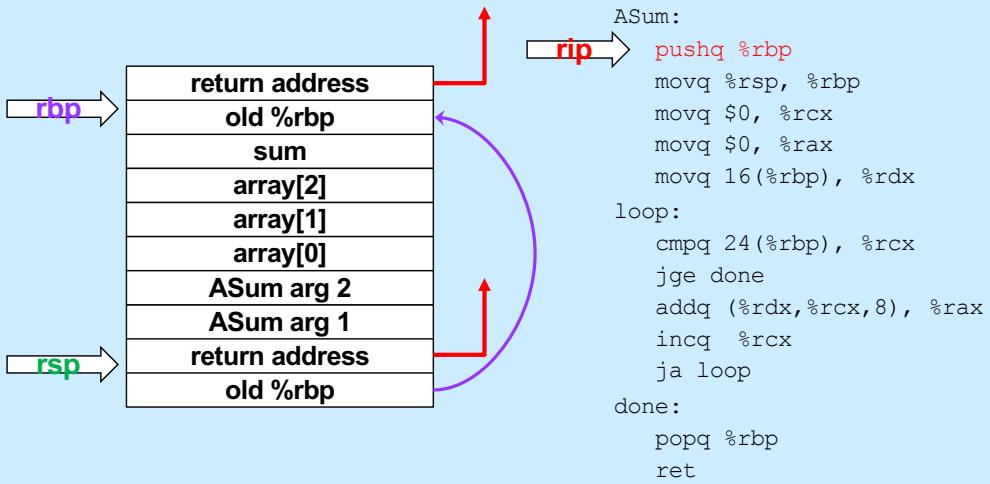

Call ASum

```
mainfunc:  
    pushq %rbp  
    movq %rsp, %rbp  
    subq $32, %rsp  
    movq $2, -32(%rbp)  
    movq $117, -24(%rbp)  
    movq $-6, -16(%rbp)  
    pushq $3  
    leaq -32(%rbp), %rax  
    pushq %rax  
    call ASum  
    addq $16, %rsp  
    movq %rax, -8(%rbp)  
    addq $32, %rsp  
    popq %rbp  
    ret
```

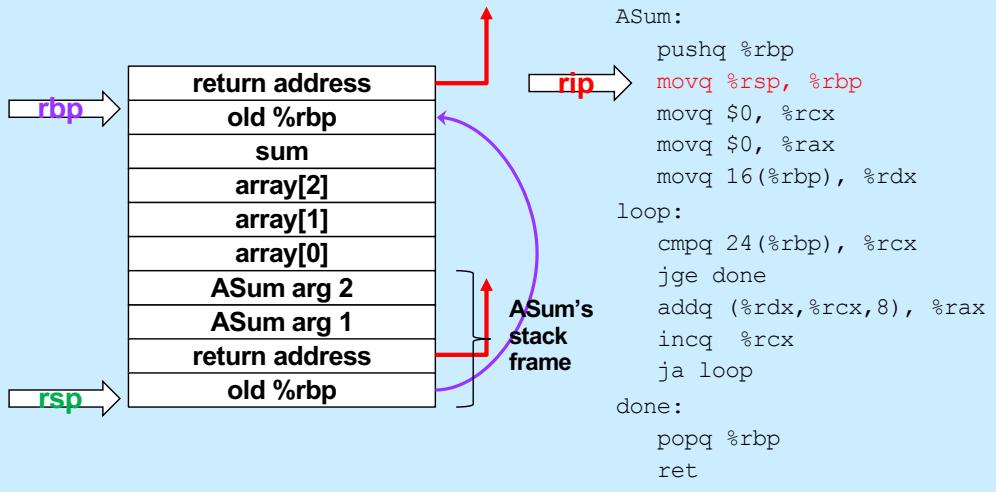

mainfunc now calls **ASum**, pushing its return address onto the stack.

Enter ASum

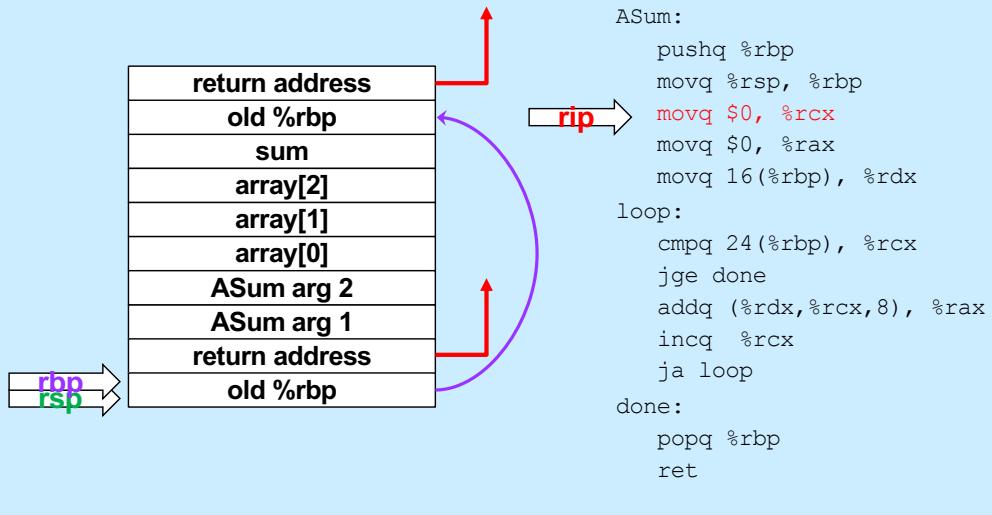

As on entry to **mainfunc**, %rbp is saved by pushing it onto the stack.

Setup Frame

%rbp is now modified to point into **ASum**'s stack frame.

Execute the Function

ASum's instructions are now executed, summing the contents of its first argument and storing the result in **%rax**.

Quiz 2

What's at 16(%rbp) (after the second instruction is executed)?

- a) a local variable
- b) the first argument to ASum
- c) the second argument to ASum
- d) something else

ASum:

```
pushq %rbp
movq %rsp, %rbp
movq $0, %rcx
movq $0, %rax
movq 16(%rbp), %rdx
loop:
    cmpq 24(%rbp), %rcx
    jge done
    addq (%rdx,%rcx,8), %rax
    incq %rcx
    ja loop
done:
    popq %rbp
    ret
```

Recall that when the function was entered, %rsp pointed to the return address (on the stack). It now points to something that's 8 bytes below that. Also recall that arguments to a function are pushed onto the stack in reverse order.
